The importance of vascular access for haemodialysis in Hallopeau-Siemens dystrophic epidermolysis bullosa

Nefrologia 2014;34(5):685-6
doi:10.3265/Nefrologia.pre2014.Apr.12466

To the Editor,

Bullous or ampullary epidermolysis is defined¹ as a group of rare inherited skin diseases characterised by a tendency

of the skin and mucous membranes to separate from the underlying tissues after minimal trauma; it is transmitted as both dominant and recessive factors and is caused by COL7A1² gene mutations: The different varieties can be grouped into three main^{1,3} types: epidermolysis bullosa simplex of dominant autosomal inheritance, junctional epidermolysis bullosa of autosomal recessive inheritance and dystrophic or dermolytic epidermolysis bullosa. Furthermore, the latter includes three forms: dominant, mild recessive, and severe recessive or Hallopeau-Siemens.

Hallopeau-Siemens dystrophic epidermolysis bullosa is the most widely severe form^{4,5}. It begins at birth with blistering of skin and mucous membranes. Blisters and vesicles heal forming atrophic scars. Extracutaneous⁴ manifestations include: dystrophy or absence of nails, sparse head hair or alopecia, excessive dental caries, microstomia, mouth ulcers, lingual tip fixation to the floor of the oral cavity, pseudosyndactylia, syndactylia and deformities of hands and feet. Furthermore the surface epithelium of the respiratory tract, gastrointestinal tract and ocular system are affected by blistering. These patients usually suffer from anaemia, malnutrition and stunting. One of the major complications of the disease is the development of chronic terminal kidney disease³, which causes early death and with the main complication of establishing an appropriate access route for dialysis.

CASE REPORT

A 31-year-old female patient was referred to dermatology for evaluation

of renal function after having been diagnosed with epidermolysis bullosa at birth and dysphagia for solid food that did not require endoscopic treatment. The endocrinology department ruled out associated hypothyroidism and suprarenal insufficiency. No previous diagnosis of chronic kidney disease in the last year, she was referred due to azotaemia. On admission: weight 45kg, height 1.55m, cutaneous pallor +, partial alopecia, a few scattered haematic crusts in the oral cavity, microstomia with lingual fixation to floor of oral cavity, generalised erythema, dermabrasion areas with blistering that did not affect the cervical region, deformities of both hands and bilateral scars and erythema (Figure 1).

Relevant laboratory abnormalities: haemoglobin 9.1g/dl, K 7.2mmol/l, urea 345mg/dl, creatinine 9.5 mg/dl, albumin 2g/dl; Urinalysis (GUE) urinary density (UD) 1009, pH 5.5, proteins +, erythrocytes 150 cells/ul; arterial blood gases: pH 7.21, PCO₂ 27, PO₂ 92%, 92% Sat, HCO₃ 7.6; 24h proteinuria 1.8g/day; urine volume: 1500cc; right kidney ultrasound 7.5 x 2.5cm and left kidney 7.1 x 2.6cm, loss of corticomedullary ratio. Electrocardiogram symmetrical peaked T waves and isolated PVCs in all precordial leads. We decided to place an indwelling tunnelled catheter due to the increased risk of infection with the Tenckhoff catheter.

Subsequent to cardiac monitoring, monitoring of non-invasive blood pressure and pulse oximetry, intravenous sedation and analgesia

Figure 1. Epidermolysis bullosa dermatological lesions seen on patient with chronic kidney disease on admittance.

was administered. Right jugular region and the exit site were identified with minimal epithelial damage, and the catheter was tunneled placing a Permacath catheter, its position was checked by means of a portable chest X-ray. Adequate arterial and venous return was achieved, and the skin (Figure 2) was sutured. Haemodialysis was started with symptom remission, patient was discharged due to clinical improvement and enrolled in the chronic haemodialysis programme.

DISCUSSION

Epidermolysis bullosa is an autosomal recessive hereditary skin disease that involves all organs from birth. Chronic kidney disease is the second leading cause of death³ in these patients after squamous cell carcinoma; it is relevant to mention that many patients die due to associated dilated cardiomyopathy⁶. Kidney disease is usually due to the development of secondary amyloidosis, IgA nephropathy, post infectious glomerulonephritis, and obstructive uropathy^{3,7}. Other factors contributing to the development of chronic kidney disease include: dehydration, dysphagia, vomiting and hypoalbuminaemia^{8,9}.

When developing chronic kidney disease, access to dialysis therapy is considered a big issue. Skin lesions and the tendency to become infected limit the use of peritoneal dialysis as an option. Another limitation to performance of an arteriovenous fistula

Figure 2. Permacath catheter permeability following corroborated procedure in urgent haemodialysis.

is the development of skin lesions and local contractions, which prevent the placement of vascular catheters⁷. Therefore, placement of a tunneled haemodialysis catheter in a central vein is, at present, considered the best option¹⁰.

Non-Hodgkin lymphoma mimicking peritonitis in a patient on peritoneal dialysis

Nefrologia 2014;34(5):686-7

doi:10.3265/Nefrologia.pre2014.Apr.12386

To the Editor,

Cloudy peritoneal fluid in peritoneal dialysis (PD) patients is most commonly due to an increase in leukocytes as an expression of bacterial peritonitis. Occasionally, when there is cloudy fluid, we must differentiate between a peritoneal infection with a negative culture and non-infectious peritoneal inflammation (sterile peritonitis).

CASE REPORT

Our patient was 59-year-old, on PD since October 2012 with a history of type 2 diabetes mellitus and chronic kidney disease secondary to diabetic nephropathy.

The patient came to the clinic with abdominal pain and cloudy peritoneal
